

The **stringstrings** Package

Extensive array of string manipulation routines for cosmetic and programming application

Steven B. Segletes
steven@arl.army.mil

2008/07/30
v1.02

Abstract

The **stringstrings** package provides a large and sundry array of routines for the manipulation of strings. The routines are developed not only for cosmetic application, such as the changing of letter cases, selective removal of character classes, and string substitution, but also for programming application, such as character look-ahead applications, argument parsing, \if- tests for various string conditions, etc. A key tenet employed during the development of this package (unlike, for comparison, the \uppercase and \lowercase routines) was to have resultant strings be “expanded” (*i.e.*, the product of an \edef), so that the **stringstrings** routines could be strung together sequentially and nested (after a fashion) to achieve very complex manipulations.

6 Commands to Test Strings	12
7 Disclaimers	14

1 Motivation

There were two seminal moments that brought about my motivation to develop this package. The first was the realization of the oft cited and infamous L^AT_EX limitation concerning the inability to nest letter-case changes with L^AT_EX's intrinsic \uppercase and \lowercase routines. The second, though not diminishing its utility in many useful applications, was the inherent limitations of the coolstr package, which is otherwise a useful tool for extracting substrings and measuring string lengths.

The former is well documented and need not be delved into in great detail. Basically, as it was explained to me, \uppercase and \lowercase are expanded by L^AT_EX at the last possible moment, and thus attempts to capture their result for subsequent use are doomed to failure. One is forced to adopt the left-to-right (rather than nested) approach to case changes.

In the case of the coolstr package, I again want to express my admiration for the utility of this package. I briefly considered building the stringstrings package around it, but it proved unworkable, because of some intrinsic limitations. First, coolstr operates on strings, not tokens, and so in order to fool it into working on tokenized inputs, one must use the cumbersome nomenclature of

```
\expandafter\substr\expandafter{\TokenizedString}{...}{...}
```

in order to, for example grab a substring of \TokenizedString. One may \def the result of this subroutine, and use it elsewhere in an unaltered state. However, one may not expand, via \edef, the result of \substr in order to use it as input to a subsequent string manipulation. And thus, the desire to engage in successive string manipulations of different natures (*e.g.*, capitalization of leading characters, extraction of words, reversal of character sequence, removal of character classes, etc., etc.) are not achievable in the context of coolstr.

It was this state of affairs that brought me to hunger for routines that could thoroughly manipulate strings, and yet produce their result “in the clear” (*i.e.*, in an untokenized form) which could be used as input for the next manipulation. It turns out the heart of the stringstrings package which achieves this goal is based on the simple (if much maligned) \if construct of L^AT_EX, by using successive iterations of the following construct:

```
\if <test char.><string><manipulated test char.>\else ... \fi
```

in which a character at the begining of a string is tested. If a match is found, the manipulated test character is replaced at the end of the string, while the original test character is lopped off from the beginning of the string. A false result is used to proceed to a different test character. In this manner, the string may be rotated through, character by character, performing the desired manipulations. And, most importantly, the product of this operation may be placed into an \edef.

It turns out there was one glitch to this process (which has been successfully remedied in the `stringstrings` package). And that is that there are several tokenized L^AT_EX symbols (*e.g.*, \\$, \{, \}, \AE, \oe, etc.) which expand to more than a single byte. If I was more savvy on L^AT_EX constructs, I would probably have known how to handle this better. But my solution was to develop my own encoding scheme wherein these problematic characters were re-encoded in my intermediate calculations as a 2-byte (escape character-escape code) combination, and only converted back into L^AT_EX symbols at the last moment, as the finalized strings were handed back to the user.

There are also several tokens, like \dag, \ddag, \P, \d, \t, \b, and \copyright which can not be put into an \edef construct. The solution developed for strings containing these such characters was to convert the encoded string not into an expanded \edef construct, but rather back into a tokenized form amenable to \def. The \retokenize command accomplishes this task and several others.

There was also one glitch that I have not yet been able to resolve to my full satisfaction, though I have provided a workaround. And that is the occurrence of L^AT_EX grouping characters, { and }, that might typically occur in math mode. The problem is that the character-rotate technique that is the core of `stringstrings` breaks when rotating these group characters. Why?? Because a string comprised of ...{....}..., during the rotation process, will eventually become ...}.....{ during an intermediate stage of character rotation. This latter string breaks L^AT_EX because it is not a properly constructed grouping, even if subsequent rotations would intend to bring it back into a proper construction.

And so, while `stringstrings` can handle certain math-mode constructs (*e.g.*, \$, ^, and _), it is unable to *directly* handle groupings that are brought about by the use of curly braces. Note that \{ and \} are handled just fine, but not { and }. As a result of this limitation regarding the use of grouping braces within strings, `stringstrings` support for various math symbols remains quite limited.

While it is also common to use curly braces to delimit the arguments of diacritical marks in words like m\"{u}de *etc.*, the same result can be achieved without the use of braces as m\"ude, with the proper result obtained: müde. For diacritical marks that have an alphabetic token such as the breve, given by \u, the curly braces can also be omitted, with the only change being a space required after the \u to delimit the token. Thus, c\u at becomes căt. Therefore, when manipulating strings containing diacritical marks, it is best to formulate them, if possible, without the use of curly braces.

The workaround fix I have developed, to provide grouping functions within `stringstrings` arguments, involves the use of newly defined tokens \LB and \RB (to be used in lieu of { and }), along with a command \retokenize. This workaround will be described subsequently, in the Disclaimers section.

2 Philosophy of Operation

There are several classes of commands that have been developed as part of the `stringstrings` package. In addition to **Configuration Commands**, which set parameters for subsequent string operations, there are the following command classes:

- **Commands to Manipulate Strings** – these commands take an input string or token and perform a specific manipulation on the string;
- **Commands to Extract String Information** – these commands take an input string or token, and ascertain a particular characteristic of the string; and
- **Commands to Test Strings** – these commands take an input string or token and test for a particular alphanumeric condition.

Of course, there are also **Support Commands** which are low-level routines which provide functionality to the package, which are generally not accessible to the user.

To support the intended philosophy that the user may achieve a complex string manipulation though a series of simpler manipulations (which is otherwise known as nesting), a mechanism had to be developed. True command nesting of the form `\commandA{\commandB{\commandC{string}}}` is **not** supported by the `stringstrings` package, since many of the manipulation commands make use of (and would thus inadvertently overwrite) the same sets of variables used by other routines. Furthermore, there is that 'ol left-to-right philosophy of L^AT_EX to contend with.

Instead, for the case of commands that manipulate strings, the expanded `\thestring` (*i.e.*, `\edef`'ed) result of the manipulation is placed into a string called `\thestring`. Then, `\thestring` may either be directly used as the input to a subsequent operation, or `\edef`'ed into another variable to save it for future use.

- String manipulation commands use an optional first argument to specify what to do with the manipulated string (in addition to putting it in `\thestring`). Most [v] string manipulation commands default to verbose mode [v], and print out their result immediately on the assumption that a simple string manipulation is, many times, all that is required. If the user wishes to use the manipulated result as is, [q] but needs to use it later in the document, a quiet mode [q] is provided which suppresses the immediate output of `\thestring`.

In the absence of symbol tokens (*e.g.*, `\$`, `\&`, `\oe`, `\^`, *etc.*), the verbose and quiet modes would prove sufficient. However, when a tokenized symbol is `\edef`'ed, the token is expanded to the actual symbolic representation of the character. If this expanded symbol is used as part of an input string to a subsequent `stringstrings` manipulation routine, it gets confused, because the means to detect the token are characteristically different than the means to detect the expanded

[e] symbol. Thus, if one wishes to use `\thestring` as an input to a subsequent manipulation routine, `stringstrings` provides an encoded mode [e] which places an encoded version of the resulting manipulation into `\thestring`. The encoded mode is also a quiet mode, since it leaves `\thestring` in a visually unappealing state that is intended for subsequent manipulation.

`\retokenize` The encoded mode is not a L^AT_EX standard, but was developed for this application. And therefore, if the result of a `stringstrings` manipulation is needed as input for a routine outside of the `stringstrings` package, the encoded mode will be of no use. For this reason (and others), the `\retokenize` command is provided. Its use is one of only three times that a `stringstrings` command returns a tokenized `\def`ed` string in `\thestring`, rather than an expanded, `\edef`ed` string. And in the other two cases, both call upon `\retokenize`.

In addition to providing tokenized strings that can be passed to other L^AT_EX packages, `\retokenize` can also remedy `stringstrings` problems associated with inadequate character encodings (OT1) and the use of grouping characters { and } within `stringstrings` arguments. This issue is discussed more fully in the Disclaimers section, and in the actual `\retokenize` command description.

Therefore, for complex multistage string manipulations, the recommended procedure is to perform each stage of the manipulation in encoded [e] mode, passing along `\thestring` to each subsequent stage of the manipulation, until the very last manipulation, which should be, at the last, performed in verbose [v] or quiet [q] modes. If the resulting manipulation is to be passed to a command outside of the `stringstrings` package for further manipulation (or if the string contains characters which cannot be placed into an `\edef`), `\thestring` may need to be `\retokenize`ed`. If concatenations of two (or more) different manipulations are to be used as input to a third manipulation, `\thestring` from the first manipulation will need to be immediately `\edef`ed` into a different variable, since `\thestring` will be overwritten by the second manipulation (see Table 1 for summary).

Table 1: **Execution Modes of `stringstrings` Commands**

Mode	Coding	Use when result is	<code>\thestring</code> is
[v] verbose	decoded or retokenized	final	echoed
[q] quiet	decoded or retokenized	final	not echoed
[e] encoded	encoded	intermediate	not echoed

`\theresult` Moving on to commands that extract string information, this class of commands (unless otherwise noted) output their result into a token which is given the name `\theresult`. This token does not contain a manipulated form of the string, but rather a piece of information about the string, such as “how many characters are in the string?”, “how many words are in the string?”, “how many letter ‘e’s are in the string?”, etc.

The final class of `stringstrings` commands are the string-test commands. While some of this class of commands also store their test result in `\theresult`, most of these commands use the `\test{condition}{string}` `\if{condition}` constructs (see `ifthen` package) to answer true/false questions like “is the string composed entirely of lowercase characters?”, “is the string’s first letter capitalized?” *etc.*

3 Configuration Commands

```
\Treatments{U-mode}{l-mode}{p-mode}{n-mode}{s-mode}{b-mode}
\defaultTreatments
\+
\?
```

`\Treatments` The command `\Treatments` is used to define how different classes of characters are to be treated by the command `\substring`, which is the brains of the `stringstrings` package. As will be explained in the next section, most string manipulation routines end up calling `\substring`, the difference between them being a matter of how these character treatments are set prior to the call. Because most string manipulation commands will set the treatments as necessary to perform their given task, and reset them to the default upon conclusion, one should set the `\Treatments` immediately prior to the call upon `\substring`.

`\Treatments` has six arguments, that define the mode of treatment for the six classes of characters that `stringstrings` has designated. All modes are one-digit integers. They are described below:

- *U-mode*— This mode defines the treatment for the upper-case characters (A–Z, œ, Å, Ø, and L). A mode of 0 tells `\substring` to remove upper-case characters, a mode of 1 indicates to leave upper-case characters alone, and a mode of 2 indicates to change the case of upper-case characters to lower case.
- *l-mode*— This mode defines the treatment for the lower-case characters (a–z, œ, æ, å, ø, l, and ß). A mode of 0 tells `\substring` to remove lower-case characters, a mode of 1 indicates to leave lower-case characters alone, and a mode of 2 indicates to change the case of lower-case characters to upper case. In the case of the eszett character (ß), there is no uppercase equivalent, and so an *l-mode* of 2 will leave the eszett unchanged.
- *p-mode*— This mode defines the treatment for the punctuation characters. `stringstrings` defines the punctuation characters as ; : ” , . ? ‘ and !. A mode of 0 tells `\substring` to remove punctuation characters, while a mode of 1 indicates to leave punctuation characters as is.
- *n-mode*— This mode defines the treatment for the numerals (0–9). A mode of 0 tells `\substring` to remove numerals, while a mode of 1 indicates to leave numerals as is.

\defaultTreatments The command `\defaultTreatments` resets all treatment modes to their default settings, which are to leave individual characters unaltered by a string manipulation.

The commands `\+` and `\?` are a pair that work in tandem to turn on `stringstrings` encoding and turn off `stringstrings` encoding, respectively. Generally, the user will not need these commands unless he is writing his own routines to take advantage of the `stringstrings` library. After `\+` is called, tokens which would otherwise expand to multi-byte sequences are instead encoded according to the `stringstrings` methodology. The affected tokens include `\$`, `\^`, `\"`, `\{`, `\}`, `_`, `\dag`, `\ddag`, `\P`, `\S`, `\ss`, `\AA`, `\aa`, `\O`, `\o`, `\AE`, `\ae`, `\OE`, `\oe`, `\~`, `\``, `\``, `\``, `\=`, `\.`, `\u`, `\v`, `\H`, `\c`, `\d`, `\t`, `\b`, `\copyright`, `\pounds`, `\L`, `\l`, and `\ss`. In addition, pipes, text carats, and hard spaces (`\~`) are encoded as well. The command `\?` restores the standard L^AT_EX encoding for these tokens.

4 Commands to Manipulate Strings

These commands take an input string or token and perform a specific manipulation on the string. They include:

```
\substring [mode] {string} {min} {max}
\caseupper [mode] {string}
\caselower [mode] {string}
\solelyuppercase [mode] {string}
\solelylowercase [mode] {string}
\changecase [mode] {string}
\noblanks [mode] {string}
\nosymbolsnumerals [mode] {string}
\alphabetic [mode] {string}
\capitalize [mode] {string}
\capitalizewords [mode] {string}
\reversestring [mode] {string}
\convertchar [mode] {string} {from-char} {to-string}
```

```

\convertword[mode]{string}{from-string}{to-string}
\rotateword[mode]{string}
\removeword[mode]{string}
\getnextword[mode]{string}
\getaword[mode]{string}{n}
\rotateleadingspaces[mode]{string}
\removeleadingspaces[mode]{string}
\stringencode[mode]{string}
\stringdecode[mode]{string}
\gobblechar[mode]{string}
\gobblechars[mode]{string}{n}
\retokenize[mode]{string}

```

Unless otherwise noted, the *mode* may take one of three values: [v] for verbose mode (generally, the default), [q] for quiet mode, and [e] for encoded mode. In all cases, the result of the operation is stored in `\thestring`. In verbose mode, it is also output immediately (and may be captured by an `\edef`). In quiet mode, no string is output, though the result still resides in `\thestring`. Encoded mode is also a quiet mode. However, the encoded mode saves the string with its `stringstrings` encodings. Encoded mode indicates that the result is an intermediate result which will be subsequently used as input to another `stringstrings` manipulation.

`\substring`

The command `\substring` is the brains of the `stringstrings` package, in that most of the commands in this section call upon `\substring` in one form or another. Nominally, the routine returns a substring of *string* between the characters defined by the integers *min* and *max*, inclusive. However, the returned substring is affected by the designated `\Treatments` which have been defined for various classes of characters. Additionally, a shorthand of \$ may be used in *min* and *max* to define END-OF-STRING, and the shorthand \${-*integer*} may be used to define an offset of *integer* relative to the END-OF-STRING.

Regardless of how many bytes a `\TeX` token otherwise expands to, or how many characters are in the token name, each `\TeX` symbol token counts as a single character for the purposes of defining the substring limits, *min* and *max*.

While the combination of `\Treatments` and `\substring` are sufficient to achieve a wide array of character manipulations, many of those possibilities are useful enough that separate commands have been created to describe them, for convenience. Several of the commands that follow fall into this category.

`\caseupper`

The command `\caseupper` takes the input string or token, and converts all lowercase characters in the string to uppercase. All other character classes are left untouched. Default mode is [v].

`\caselower`

The command `\caselower` takes the input string or token, and converts all uppercase characters in the string to lowercase. All other character classes are left untouched. Default mode is [v].

`\solelyuppercase`

The command `\solelyuppercase` is similar to `\caseupper`, except that all

	punctuation, numerals, and symbols are discarded from the string. Blankspaces are left alone, and lowercase characters are converted to uppercase. Default mode is [v].
\solelylowercase	The command \solelylowercase is similar to \caselower, except that all punctuation, numerals, and symbols are discarded from the string. Blankspaces are left alone, and uppercase characters are converted to lowercase. Default mode is [v].
\changecase	The command \changecase switches lower case to upper case and upper case to lower case. All other characters are left unchanged. Default mode is [v].
\noblanks	The command \noblanks removes blankspaces (both hard and soft) from a string, while leaving other characters unchanged. Default mode is [v].
\nosymbolsnumerals	The command \nosymbolsnumerals removes symbols and numerals from a string, while leaving other characters unchanged. Default mode is [v].
\alphabetic	The command \alphabetic discards punctuation, symbols, and numerals, while retaining alphabetic characters and blankspaces. Default mode is [v].
\capitalize	The command \capitalize turns the first character of <i>string</i> into its upper case, if it is alphabetic. Otherwise, that character will remain unaltered. Default mode is [v].
\capitalizewords	The command \capitalizewords turns the first character of every word in <i>string</i> into its upper case, if it is alphabetic. Otherwise, that character will remain unaltered. For the purposes of this command, “the first character of a word” is defined as either the first character of the string, or the first non-blank character that follows one or more blankspaces. Default mode is [v].
\reversestring	The command \reversestring reverses the sequence of characters in a string, such that what started as the first character becomes the last character in the manipulated string, and what started as the last character becomes the first character. Default mode is [v].
\convertchar	The command \convertchar is a substitution command in which a specified match character in the original string (<i>from-char</i>) is substituted with a different string (<i>to-string</i>). All occurrences of <i>from-char</i> in the original string are replaced. The <i>from-char</i> can only be a single character (or tokenized symbol), whereas <i>to-string</i> can range from the null-string (<i>i.e.</i> , character removal) to a single character (<i>i.e.</i> , character substitution) to a complete multi-character string. Default mode is [v].
\convertword	The command \convertword is a substitution command in which a specified match string in the original string (<i>from-string</i>) is substituted with a different string (<i>to-string</i>). All occurrences of <i>from-string</i> in the original string are replaced. Default mode is [v].
\rotateword	The command \rotateword takes the first word of <i>string</i> (and its leading and trailing spaces) and rotates them to the end of the string. Care must be taken to have a blankspace at the beginning or end of <i>string</i> if one wishes to retain a blankspace word separator between the original last word of the string and the

<code>\removeword</code>	The command <code>\removeword</code> removes the first word of <i>string</i> , along with any of its leading and trailing spaces. Default mode is [v].
<code>\getnextword</code>	The command <code>\getnextword</code> returns the next word of <i>string</i> . In this case, “word” is a sequence of characters delimited either by spaces or by the beginning or end of the string. Default mode is [v].
<code>\getword</code>	The command <code>\getword</code> returns a word of <i>string</i> defined by the index, <i>n</i> . In this case, “word” is a sequence of characters delimited either by spaces or by the first or last characters of the string. If the index, <i>n</i> , requested exceeds the number of words available in the string, the index wraps around back to the first argument of the string, such that asking for the tenth word of an eight word string will return the second word of the string. Default mode is [v].
<code>\rotateleadingspaces</code>	The command <code>\rotateleadingspaces</code> takes any leading spaces of the string and rotates them to the end of the string. Default mode is [v].
<code>\removeleadingspaces</code>	The command <code>\removeleadingspaces</code> removes any leading spaces of the string. Default mode is [v].
<code>\stringencode</code>	The command <code>\stringencode</code> returns a copy of the string that has been encoded according to the <code>stringstrings</code> encoding scheme. Because an encoded string is an intermediate result, the default mode for this command is [e].
<code>\stringdecode</code>	The command <code>\stringdecode</code> returns a copy of the string that has been decoded. Default mode is [v].
<code>\gobblechar</code>	The command <code>\gobblechar</code> returns a string in which the first character of <i>string</i> has been removed. Unlike the L ^A T _E X system command <code>\@gobble</code> which removes the next byte in the input stream, <code>\gobblechar</code> not only takes an argument as the target of its gobble, but also removes one character , regardless of whether that character is a single-byte or multi-byte character. Because this command may have utility outside of the <code>stringstrings</code> environment, the result of this command is retokenized (<i>i.e.</i> , <code>def</code> 'ed) rather than expanded (<i>i.e.</i> , <code>edef</code> 'ed). Default mode is [q]. Mode [e] is not recognized.
<code>\gobblechars</code>	The command <code>\gobblechars</code> returns a string in which the first <i>n</i> characters of <i>string</i> have been removed. Like <code>\gobblechar</code> , <code>\gobblechars</code> removes characters, regardless of whether those characters are single-byte or multi-byte characters. Likewise, the result of this command is retokenized (<i>i.e.</i> , <code>def</code> 'ed) rather than expanded (<i>i.e.</i> , <code>edef</code> 'ed). Default mode is [q]. Mode [e] is not recognized.
<code>\retokenize</code>	The command <code>\retokenize</code> takes a string that is encoded according to the <code>stringstrings</code> encoding scheme, and repopulates the encoded characters with their L ^A T _E X tokens. This command is particularly useful for exporting a string to a routine outside of the <code>stringstrings</code> library or if the string includes the following characters: <code>\{</code> , <code>\}</code> , <code>\ </code> , <code>\dag</code> , <code>\ddag</code> , <code>\d</code> , <code>\t</code> , <code>\b</code> , <code>\copyright</code> , and <code>\P</code> . Default mode is [q]. Mode [e] is not recognized.

5 Commands to Extract String Information

These commands take an input string or token, and ascertain a particular characteristic of the string. They include:

```
\stringlength[mode]{string}
\findchars[mode]{string}{match-char}
\findwords[mode]{string}{match-string}
\whereischar[mode]{string}{match-char}
\whereisword[mode]{string}{match-string}
\wordcount[mode]{string}
\getargs[mode]{string}
```

Commands in this section return their result in the string `\theresult`, unless otherwise specified. Unless otherwise noted, the *mode* may take one of two values: [v] for verbose mode (generally, the default), and [q] for quiet mode. In both cases, the result of the operation is stored in `\theresult`. In verbose mode, it is also output immediately (and may be captured by an `\edef`). In quiet mode, no string is output, though the result still resides in `\theresult`.

- | | |
|----------------------------|---|
| <code>\stringlength</code> | The command <code>\stringlength</code> returns the length of <i>string</i> in characters (not bytes). Default mode is [v]. |
| <code>\findchars</code> | The command <code>\findchars</code> checks to see if the character <i>match-char</i> occurs anywhere in <i>string</i> . The number of occurrences is stored in <code>\theresult</code> and, if in verbose mode, printed. If it is desired to find blankspaces, <i>match-char</i> should be set to <code>{~}</code> and not <code>{ }{ }</code> . Default mode is [v]. |
| <code>\findwords</code> | The command <code>\findwords</code> checks to see if the string <i>match-string</i> occurs anywhere in <i>string</i> . The number of occurrences is stored in <code>\theresult</code> and, if in verbose mode, printed. If it is desired to find blankspaces, those characters in <i>match-string</i> should be set to hardspaces (<i>i.e.</i> , tildes) and not softspaces (<i>i.e.</i> , blanks), regardless of how they are defined in <i>string</i> . Default mode is [v]. |
| <code>\whereischar</code> | The command <code>\whereischar</code> checks to see where the character <i>match-char</i> first occurs in <i>string</i> . The location of that occurrence is stored in <code>\theresult</code> and, if in verbose mode, printed. If the character is not found, <code>\theresult</code> is set to a value of 0. If it is desired to find blankspaces, <i>match-char</i> should be set to <code>{~}</code> and not <code>{ }{ }</code> . Default mode is [v]. |
| <code>\whereisword</code> | The command <code>\whereisword</code> checks to see where the string <i>match-string</i> first occurs in <i>string</i> . The location of that occurrence is stored in <code>\theresult</code> and, if in verbose mode, printed. If <i>match-string</i> is not found, <code>\theresult</code> is set to a value of 0. If it is desired to find blankspaces, those characters in <i>match-string</i> should be set to hardspaces (<i>i.e.</i> , tildes) and not softspaces (<i>i.e.</i> , blanks), regardless of how they are defined in <i>string</i> . Default mode is [v]. |
| <code>\wordcount</code> | The command <code>\wordcount</code> counts the number of space-separated words that occur in <i>string</i> . Default mode is [v]. |
| <code>\getargs</code> | The command <code>\getargs</code> mimics the Unix command of the same name, in |

that it parses *string* to determine how many arguments (*i.e.*, words) are in *string*, and extracts each word into a separate variable. The number of arguments is placed in `\nargs` and the individual arguments are placed in variables of the name `\argi`, `\argii`, `\argiii`, `\argiv`, etc. This command may be used to facilitate simply the use of multiple optional arguments in a L^AT_EX command, for example `\mycommand[option1 option2 option3]{argument}`. In this case, `\mycommand` should exercise `\getargs{\#1}`, with the result being that *option1* is stored in `\argi`, *etc.* The command `\mycommand` may then proceed to parse the optional arguments and branch accordingly. Default mode is `[q]`; `[e]` mode is permitted, while `[v]` mode is disabled.

6 Commands to Test Strings

These commands take an input string or token and test for a particular alphanumeric condition. They include:

```
\isnextbyte[mode]{match-byte}{string}
\testmatchingchar{string}{n}{match-char}
\testcapitalized{string}
\testuncapitalized{string}
\testleadingalpha{string}
\testuppercase{string}
\testsolelyuppercase{string}
\testlowercase{string}
\testsolelylowercase{string}
\testalphabetic{string}
```

\isnextbyte The command `\isnextbyte` tests to see if the first byte of *string* equals *match-byte*. It is the only string-testing command in this section which does not use the `ifthen` test structure for its result. Rather, `\isnextbyte` returns the result of its test as a T or F in the string `\theresult`. More importantly, and unlike other `stringstrings` commands, `\isnextbyte` is a *byte* test and not a *character* test. This means that, while `\isnextbyte` operates very efficiently, it cannot be used to directly detect multi-byte characters like `\$`, `\^`, `\{`, `\}`, `_`, `\dag`, `\ddag`, `\AE`, `\ae`, `\OE`, `\oe`, *etc.* (`\isnextbyte` will give false positives or negatives when testing for these multi-byte characters). The default mode of `\isnextbyte` is `[v]`.

\testmatchingchar If a character needs to be tested, rather than a byte, `\testmatchingchar` should be used. The command `\testmatchingchar` is used to ascertain whether character *n* of *string* equals *match-char* or not. Whereas `\isnextbyte` checks only a *byte*, `\testmatchingchar` tests for a *character* (single- or multi-byte character). After the test is called, the action(s) may be called out with `\ifmatchingchar true-code \else false-code \fi`.

\testcapitalized The command `\testcapitalized` is used to ascertain whether the first character of *string* is capitalized or not. If the first character is non-alphabetic, the test will return FALSE. After the test is called, the action(s) may be called out

	with <code>\ifcapitalized true-code \else false-code \fi</code> .
<code>\testuncapitalized</code>	The command <code>\testuncapitalized</code> is used to ascertain whether the first character of <i>string</i> is uncapitalized. If the first character is non-alphabetic, the test will return FALSE. After the test is called, the action(s) may be called out with <code>\ifuncapitalized true-code \else false-code \fi</code> .
<code>\testleadingalpha</code>	The command <code>\testleadingalpha</code> is used to ascertain whether the first character of <i>string</i> is alphabetic. After the test is called, the action(s) may be called out with <code>\ifleadingalpha true-code \else false-code \fi</code> .
<code>\testuppercase</code>	The command <code>\testuppercase</code> is used to ascertain whether all the alphabetic characters in <i>string</i> are uppercase or not. The presence of non-alphabetic characters in <i>string</i> does not falsify the test, but are merely ignored. However, a string completely void of alphabetic characters will always test FALSE. After the test is called, the action(s) may be called out with <code>\ifuppercase true-code \else false-code \fi</code> .
<code>\testsolelyuppercase</code>	The command <code>\testsolelyuppercase</code> is used to ascertain whether <i>all</i> the characters in <i>string</i> are uppercase or not. The presence of non-alphabetic characters in <i>string</i> other than blankspaces will automatically falsify the test. Blankspaces are ignored. However, a null string or a string composed solely of blankspaces will also test FALSE. After the test is called, the action(s) may be called out with <code>\ifsolelyuppercase true-code \else false-code \fi</code> .
<code>\testlowercase</code>	The command <code>\testlowercase</code> is used to ascertain whether all the alphabetic characters in <i>string</i> are lowercase or not. The presence of non-alphabetic characters in <i>string</i> does not falsify the test, but are merely ignored. However, a string completely void of alphabetic characters will always test FALSE. After the test is called, the action(s) may be called out with <code>\iflowercase true-code \else false-code \fi</code> .
<code>\testsolelylowercase</code>	The command <code>\testsolelylowercase</code> is used to ascertain whether <i>all</i> the characters in <i>string</i> are lowercase or not. The presence of non-alphabetic characters in <i>string</i> other than blankspaces will automatically falsify the test. Blankspaces are ignored. However, a null string or a string composed solely of blankspaces will also test FALSE. After the test is called, the action(s) may be called out with <code>\ifsolelylowercase true-code \else false-code \fi</code> .
<code>\testalphabetic</code>	The command <code>\testalphabetic</code> is used to ascertain whether <i>all</i> the characters in <i>string</i> are alphabetic or not. The presence of non-alphabetic characters in <i>string</i> other than blankspaces will automatically falsify the test. Blankspaces are ignored. However, a null string or a string composed solely of blankspaces will also test FALSE. After the test is called, the action(s) may be called out with <code>\ifaxalphabetic true-code \else false-code \fi</code> .

7 Disclaimers

Now that we have described the commands available in the `stringstrings` package, it is appropriate to lay out the quirks and warnings associated with the use of the package.

`\@MAXSTRINGSIZE` First, `stringstrings` is currently set to handle a string no larger than 500 characters. A user could circumvent this, presumably, by editing the style package to increase the value of `\@MAXSTRINGSIZE`.

It is important to remember that `stringstrings` follows the underlying rules of L^AT_EX. Therefore, a passed string could not contain a raw % as part of it, because it would, in fact, comment out the remainder of the line. Naturally, the string may freely contain instances of %.

Tokens that take two or more characters to express (*e.g.*, `\#`, `\oe`, `\ddag`, *etc.*) are **counted as a single character** within the string. The rule applies if you wanted to know the length of a string that was populated with such tokens, or wanted to extract a substring from a such a string. Of course, the exception that makes the rule is that of diacritical marks, which count as separate symbols from the characters they mark. For example, `\^a` counts as two characters, because the `a` is really just the operand of the `\^` token, even though the net result looks like a single character (â).

Consistent with L^AT_EX convention, groups of spaces are treated as a single blankspace, unless encoded with ~ characters. And finally, again consistent with the way L^AT_EX operates, the space that follows an alphabetic token is not actually a space in the string, but serves as the delimiter to the token. Therefore, `\OE` dipus (Edipus) has a length of six characters, one for the `\OE` and five for the dipus. The intervening space merely closes out the `\OE` token, and does not represent a space in the middle of the string.

One quirk worthy of particular note concerns the tabbing character, meaning & as opposed to \& (which is handled without problem). As of version 1.01, `stringstrings` has the capability to operate on arguments containing the ampersand &, normally reserved as the L^AT_EX tabbing character. However, one adverse by-product is that & characters returned in `\thestring` lose their catcode-4 value, and thus lose their ability to function as tabbing characters. In the following example,

```
\caseupper[q]{a & b & c & d}
\begin{tabular}{|l|c|c|c|} \hline
\thestring\\ \hline
\end{tabular}
```

will produce

A	&	B	&	C	&	D
---	---	---	---	---	---	---

 instead of the desired

A		B		C		D
---	--	---	--	---	--	---

.

In the `\substring` command, no tests are performed to guarantee that the lower limit, *min*, is less than the upper limit, *max*, or that *min* is even positive. However, the upper limit, *max*, is corrected, if set larger than the string length. Also, the use of the ‘\$’ symbol to signify the last character of the string and ‘\$–*n*’ to denote an offset of *n* characters from the end of the string can be helpful in avoiding the misindexing of strings.

Table 2 shows a variety of characters and tokens, some of which pose a challenge to `stringstrings` manipulations. In all cases, a solution or workaround is provided. For symbols in the top two categories, the workaround solution includes the use of retokenized strings instead of expanded strings. For symbols in the next two categories, use of T1 encoding or retokenizing provides a satisfactory solution. In the bottom two categories, because of `stringstrings` encoded [e] mode, there is nothing to impede the use of these characters in `stringstrings` arguments, if encoded [e] mode is employed for intermediate calculations. Some of the details of these problematic cases is described below.

Not surprisingly, you are not allowed to extract a substring of a string, if it breaks in the middle of math mode, because a substring with only one \$ in it cannot be `\edef`'ed.

There are a few potential quirks when using L^AT_EX's native OT1 character encoding, most of which can be circumvented by using the more modern T1 encoding (accessed via `\renewcommand\encodingdefault{T1}` in the document preamble). The quirks arise because there are several characters that, while displayable in L^AT_EX, are not part of the OT1 character encoding. The characters include \{, \}, and the | symbol (accessed in `stringstrings` via \|). When using `stringstrings` to manipulate strings containing these characters in the presence of OT1 encoding, they come out looking like –, ", and —, respectively. However, if the T1 encoding fix is not an option for you, you can also work around this problem by `\retokenize`'ing the affected string (the `\retokenize` command is provided to convert encoded, expanded strings back into tokenized form, if need be).

Likewise, for both OT1 and T1 encoding, the characters † (\dag), ‡ (\ddag), ¶ (\P), . (\d), ^ (\t), _ (\b), and © (\copyright) cannot be in the argument of an `\edef` expression. For manipulated strings including these characters, `\retokenize` is the only option available to retain the integrity of the string.

As discussed thoroughly in the previous section, an “encoded” form of the string manipulation routines is provided to prevent the undesirable circumstance of passing an `\edef`'ed symbol as input to a subsequent manipulation. Likewise, never try to “decode” an already “decoded” string.

When `stringstrings` doesn't understand a token, it is supposed to replace it with a period. However, some undecipherable characters may inadvertently be replaced with a space, instead. Of course, neither of these possibilities is any comfort to the user.

As mentioned already, `stringstrings` cannot handle curly braces that are used for grouping purposes, a circumstance which often arises in math mode. Nonetheless,

Table 2: Problematic Characters/Tokens and `stringstrings` Solutions

LATEX	Symbol/Name	Problem/Solution
{ }	begin group end group	Cannot use { and } in <code>stringstrings</code> arguments. However, use \LB... \RB in lieu of {...}; manipulate string in [e] mode & \retokenize
\dag \ddag \P \d \t \b \copyright	† Dagger ‡ Double Dagger ¶ Pilcrow ¤ Underdot ×× Joining Arch ₓ Letter Underline © Copyright	Cannot \edef these tokens; Thus, [v] mode fails with both OT1 and T1 encoding; manipulate string in [e] mode & \retokenize
_ \{ \} \\$ \c \pounds	_ Underscore { Left Curly Brace } Right Curly Brace § Section Symbol ₓ Cedilla £ Pounds	Cannot \edef with OT1 encoding; either \renewcommand\encodingdefault{T1}, or manipulate string in [e] mode & \retokenize. With OT1, \\$, \c and \pounds break <code>stringstrings</code> [v] mode.
\	stringstrings Pipe Char. (T1) — (OT1)	Distinct from , the <code>stringstrings</code> encoded-escape character
\\$ \carat \^ \' \" \~ \` \. \=	\$ Dollar ^ (text mode) ˆ Circumflex acute Acute umlaut Umlaut tilde Tilde grave Grave overdot Overdot macron Macron	Either cannot \edef, or cannot identify uniquely with \if construct, or expanded character is more than one byte. <i>However,</i> Use these characters freely, <code>stringstrings</code> encoding functions transparently with them. \retokenize also works
\u \v \H \ss \AE \ae \OE \oe \AA \aa \O \o \L \l \~	ˇ Breve ˇ Caron ˇ Double Acute ˇ Eszett Æ æ æsc Œ œ œthel Å å angstrom Ø ø slashed O Ł ł barred L Hardspace	
\$ ~ -	begin/end math mode math superscript math subscript	These characters pose no difficulties; However, cannot extract substring that breaks in middle of math mode. Other math mode symbols NOT supported.
&	ampersand	Version 1.01 <code>stringstrings</code> can manipulate the ampersand. However, returned strings containing the & character lose their catcode-4 status, making them unfit for use as tabbing characters.

\LB and \RB may be used within `stringstrings` arguments in lieu of grouping braces, if the final result is to be retokenized. Thus, `\caselower[e]{\$X^\LB Y + Z\RB$}` followed by `\convertchar[e]{\thestring}{x}{(1+x)}`, when finished up with the following command, `\retokenize[v]{\thestring}` yields as its result: $(1 + x)^y + z$.

One might ask, “why not retokenize everything, instead of using the [v] mode of the `stringstrings` routines?” While one could do this, the answer is simply that `\retokenize` is a computationally intensive command, and that it is best used, therefore, only when the more efficient methods will not suffice. In many, if not most cases, strings to be manipulated will be solely composed of alphanumeric characters which don’t require the use of `\retokenize`, T1 encoding, or even `stringstrings` encoding.

Despite these several disclaimers and workarounds required when dealing with problematic characters, I hope you find the `stringstrings` architecture and feel to be straightforward and useful. There is only one thing left, and that is to dissect the code... and so here we go.

`stringstrings.sty` 8 Code Listing

I’ll try to lay out herein the workings of the `stringstrings` style package.

```
1 <*package>
2

397 %%% COMMANDS TO MANIPULATE STRINGS %%%%%% %%%%%% %%%%%% %%%%%% %%%%%% %%%%%% %%%%%%

```

In the next group of commands, the result is always stored in an expandable string, `\thestrings`. Expandable means that `\thestrings` can be put into a subsequent `\edef{}` command. Additionally, the optional first argument can be used to cause three actions (verbose, encoded, or quiet):

```

= v \thestrings is decoded (final result); print it immediately (default)
= e \thestrings is encoded (intermediate result); don't print it
= q \thestrings is decoded (final result), but don't print it

```

`\substring` The command `\substring` is the brains of this package... It is used to acquire a substring from a given string, along with performing specified character manipulations along the way. Its strategy is fundamental to the `stringstrings` package: sequentially rotate the 1st character of the string to the end of the string, until the desired substring resides at end of rotated string. Then, gobble up the leading part of string until only the desired substring is left.

```
398 \newcommand{\substring}[4] [v]{\+%
```

Obtain the string length of the string to be manipulated and store it in `@stringsize`.

```
399  \@getstringlength{#2}{@stringsize}%

```

First, `\@decodepointer` is used to convert indirect references like `$` and `$-3` into integers.

```

400  \@decodepointer{#3}%
401  \setcounter{@fromindex}{\@fromtoindex}%
402  \@decodepointer{#4}%
403  \setcounter{@toindex}{\@fromtoindex}%

```

Determine the number of characters to rotate to the end of the string and the number of characters to then gobble from it, in order to leave the desired substring.

```

404  \setcounter{@gobblesize}{\value{@stringsize}}%
405  \ifthenelse{\value{@toindex} > \value{@stringsize}}{%

```

```

406      {\setcounter{@maxrotation}{\value{@stringsize}}}%  

407      {\setcounter{@maxrotation}{\value{@toindex}}}%  

408      \addtocounter{@gobblesize}{-\value{@maxrotation}}%  

409      \addtocounter{@gobblesize}{\value{@fromindex}}%  

410      \addtocounter{@gobblesize}{-1}%

```

Prepare for the string rotation by initializing counters, setting the targeted string into the working variable, `\rotatingword`, and set the encoding treatment specified.

```

411  \setcounter{@letterindex}{0}%  

412  \edef\rotatingword{\#2}%  

413  \def\EncodingTreatment{\#1}%

```

If capitalization (first character of string or of each word) was specified, the trigger for 1st-character capitalization will be set. However, the treatments for the alphabetic characters for the remainder of the string must be saved and reinstated after the first character is capitalized.

```

414  \if 0\CapitalizeString%  

415 %  DO NOT SET CAPITALIZE TRIGGER FOR FIRST CHARACTER  

416  \setcounter{@captrigger}{0}%  

417  \else

438             \setcounter{@capstrigger}{2}%
439         \fi
440     \fi

```

Is the next character an encoded symbol? If it is a normal character, simply rotate it to the end of the string. If it is an encoded symbol however, its treatment will depend on whether it will be gobbled away or end up in the final substring. If it will be gobbled away, leave it encoded, because the gobbling routine knows how to gobble encoded characters. If it will end up in the substring, manipulate it according to the encoding rules set in `\@defineactions` and rotate it.

```

441 %  CHECK IF NEXT CHARACTER IS A SYMBOL
442     \isnextbyte[q]{\EscapeChar}{\rotatingword}%
443     \ifthenelse{\value{@letterindex} < \value{@fromindex}}%

488 }%

```

The loop has ended.

Gobble up the first `@gobblesize` characters (not bytes!) of the string, which should leave the desired substring as the remainder. If the mode is verbose, print out the resulting substring.

```

489 % GOBBLE AWAY THAT PART OF STRING THAT ISN'T PART OF REQUESTED SUBSTRING
490   \gobblearg{\rotatingword}{\arabic{@gobblesize}}%
491   \edef\thestring{\gobbledword}%
492   \if v#1\thestring\fi%
493 \?}

```

Many of the following commands are self-explanatory. The recipe they follow is to use `\Treatments` to specify how different character classes are to be manipulated, and then to call upon `\substring` to effect the desired manipulation. Treatments are typically re-defaulted at the conclusion of the command, which is why the user, if desiring special treatments, should specify those treatments immediately before a call to `\substring`.

\gobblechars Remove first #3 characters (not bytes!) from string #2. Unlike just about all other `stringstrings` commands, result is retokenized and not expanded.

```
658 % USER CALLABLE VERSION OF \@gobblearg. TURNS ON REENCODING.
659 % GOBBLE FIRST #3 CHARACTERS FROM STRING #2. TWO-BYTE
660 % ESCAPE SEQUENCES, WHEN ENCONTERED, COUNT AS A SINGLE GOBBLE.
661 \newcommand\gobblechars[3] [q]{\+%
662   \@gobblearg{#2}{#3}%
663   \?\retokenize[#1]{\gobbledword}%
664 }
```

\retokenize One of the key `stringstrings` routines that provides several indispensable functions. Its function is to take an encoded string #2 that has been given, and repopulate the string with its L^AT_EX tokens in a `\def` form (not an expanded `\edef` form). It is useful if required to operate on a string outside of the `stringstrings` library routines, following a `stringstrings` manipulation. It is also useful to display certain tokens which cannot be manipulated in expanded form. See Table 2 for a list of tokens that will only work when the resulting string is retokenized (and not expanded).

Logic: Loop through each character of given string #2. Each successive character of the string is retokenized as `\inexttoken`, `\iinexttoken`, `\iiinexttoken`, `\ivnexttoken`, etc., respectively. Then a series of strings are formed as

```
\def\builddtoken{}
\def\builddtokeni{\builtoken\inexttoken}
\def\builddtokenii{\builtokeni\iinexttoken}
\def\builddtokeniii{\builtokenii\iiinexttoken}
\def\builddtokeniv{\builtokeniii\ivnexttoken}
```

The last in the sequence of `\builtoken...` strings (renamed `\builddtokenq`) is the retokenized version of string #2.

```
665 % CONVERTS ENCODED STRING BACK INTO TOKENIZED FORM (i.e., def'ED).
666 \newcommand\retokenize[2] [q]{\+%
667   \edef\@svstring{#2}%

```

881 %%%%%% COMMANDS TO TEST STRINGS %%%%%% %%%%%% %%%%%% %%%%%% %%%%%%

The following group of commands test for various alphanumeric string conditions.

\isnextbyte This routine performs a simple test to determine if the first byte of string #3 matches the byte given by #2. The only problem is that the test can produce a false negative if the first byte of the test string equals the match byte and the second byte of the test string equals the **SignalChar** (defined below).

To resolve this possibility, the test is performed twice with two different values for **\SignalChar**, only one of which can produce a false negative for a given test string. If the two results match, then that result gives the correct answer to the question of whether the first byte of #3 equals #2. If, however, the two results fail to match, then one can assume that one of the results is a false negative, and so a “true” condition results.

The following two “signal characters,” used for the two tests, can be any two distinct characters. They are used solely by **\isnextbyte**.

```

882 \def\PrimarySignalChar{@}
883 \def\SecondarySignalChar{'}
884
885 % \isnextbyte NEEDS TO OPERATE IN RAW (SINGLE BYTE) MODE SO AS TO
886 % PERFORM TESTS FOR PRESENCE OF \EscapeChar

```

Incidentally, **\isnextbyte** can and is used by **stringstrings** to detect multi-byte characters in a manner which may also be employed by the user. To do this: First, the string to be tested should be encoded. Then, **\isnextbyte** may be used to check for **\EscapeChar** which is how every multi-byte character will begin

its encoding by the `stringstrings` package. If `\EscapeChar` is detected as the next character, then the string to test may have its leading byte gobbled and the next character (called the Escape Code) may be tested, and compared against the known `stringstrings` escape codes. The combination of Escape-Character/Escape-Code is how all multi-byte characters are encoded by the `stringstrings` package.

```
887 \newcommand{\isnextbyte}[3][v]{%
```

Here's the first test...

```
888 \let\SignalChar\PrimarySignalChar%
889 \edef\x{\if #2#3\else\SignalChar\fi}%
890 \edef\x{\if \SignalChar\x F\else T\x\fi}%
```

... and the second

```
891 \let\SignalChar\SecondarySignalChar%
892 \edef\y{\if #2#3\else\SignalChar\fi}%
893 \edef\y{\if \SignalChar\y F\else T\y\fi}%
```

If the two tests produced the same result, then a comparison of `\x\y` and `\y\x` will show it.

```
894 % BECAUSE THE METHOD ONLY PRODUCES FALSE NEGATIVES, IF RESULTS DON'T
895 % AGREE FROM USING TWO DIFFERENT SIGNAL CHARACTERS, RESULT MUST BE TRUE.
896 \ifthenelse{\equal{\x\y}{\y\x}}{
897   {\edef\theresult{\x}}%
898 % CORRECT THE FALSE NEGATIVE
899   {\edef\theresult{T}}%
900 \if q#1\else\theresult\fi
901 }
```

`\testmatchingchar` This routine checks for a specified match-character within a target string. Unlike `\isnextbyte`, this routine checks for characters (single- or multi-byte) and not just individual bytes. Additionally, rather than testing the match-character against the first byte of the test-string, the user specifies (through #2) which byte of the test-string should be compared to the match-character.

This routine is not as efficient as `\isnextbyte`, but much more versatile.

```
902 % CHECKS TO SEE IF [#2]'th CHARACTER IN STRING [#1] EQUALS [#3]
903 % RESULT STORED IN BOOLEAN \ifmatchingchar

```

`\@getnextword` A low-level routine designed to extract the next [space-delimited] word of the primary argument. It has several quirks: if the passed string has one leading space, it is included as part of next word. If it has two leading [hard]spaces, the 2nd hard space *is* the next word. Using the higher-level `\getnextword` deals automatically with these abberant possibilities.

```

1149 \newcommand{\@getnextword}[2] {%
1150   \defaultTreatments%
1151   \def\SeekBlankSpace{2}%
1152   \substring[#1]{#2}{1}{\MAXSTRINGSIZE}%
1153   \def\SeekBlankSpace{0}%
1154 }

```

`\@retokenizechar` This command is the guts of the retokenize command. It grabs the character provided in string #1 and assigns it to a unique token whose name is created from the string #2. The command has two primary `\if` branches. The first branch is taken if the character is a special two-byte-encoded escape-sequence, while the second branch is taken if the character is a &, %, #, a blankspace, or any simple

one-byte character.

```

```

\@rotate The following code is the engine of the string manipulation routine. It is a tree of successive L^AT_EX commands (each of which is composed of an \if... cascade) which have the net effect of rotating the first letter of the string into the last position. Depending on modes set by \@defineactions and \@defaultTreatments, the leading character is either encoded, decoded, or removed in the process. Note: \@rotate loses track of double/multi-spaces, per L^AT_EX convention, unless encoded blanks (~) are used.

```
